Abstract

In order to evaluate strength reliability of micron size polycrystalline silicon (poly-Si) structure for microelectromechanical systems (MEMS), bending strength tests of cantilever beam, Weibull analysis of the strength and fracture surface analysis are performed. Recently, the importance of MEMS in society is increasing, and the number of production is also increasing. MEMS devices, which contain mechanical movement, have to maintain their reliability in face of external shock, thermal stress and residual stress from manufacturing processes. When the age of the MEMS mass production comes, in case the material strength design of MEMS is performed, required strength data is not average value but the variation, especially minimum value assumed of the structure and material. Then, in order to evaluate strength reliability of micron size poly-Si structure, tests and analysis are performed. The specimen is made by chemical vapor deposition (CVD) process and the thickness is 3.5, 6.4 and 8.3 [μm] and the specimen has notch (stress concentration). The test specimen used for the test changed characteristics of (1) film thickness (2) stress concentration, and investigation about the influence each effect of the variation in a bending strength with fracture surface analysis are discussed.

Keywords: Polycrystalline silicon, Strength, Reliability, Stress concentration, Weibull analysis, Effective surface area

1. Introduction

Polycrystalline silicon (poly-Si) structure is widely employed in the Micro-Electro-Mechanical Systems (MEMS) 1, 2. MEMS devices, which contain mechanical movement, have to maintain their reliability in face of external shock, thermal stress and residual stress from manufacturing processes, and fracture will begin mainly in stress concentration area. Therefore, it is necessary to build up reliability design criterion of the poly-Si structure that has stress concentration 3-9. On the other hand, in mass production of MEMS products, it is also important to control the quality considering the reliability of poly-Si structure, which has scattered strength. Thus, we have to clarify the stress concentration effect on strength and the scatter of the strength of the poly-Si
structure. In order to clarify these subjects, bending tests using micro scale cantilever beams with or without notch of several sizes are performed.

2. Test Method and Results

2.1 Specimen and test method

The specimens are illustrated in Fig. 1, and the photographs of specimens are shown in Fig. 2. Shapes and dimensions of the specimens are shown in Table 1. For bending tests, two types of specimens; Type-A and B are prepared. In the Type-A specimen, the notch of several sizes (1~5 [μm]) is introduced in the root section of micro-cantilever beam. In the Type-B, by the microscopic observation, the 1μm corner radius is recognized indeed in the root section of microcantilever beam. And the thickness of the specimen is 3.5, 6.4 and 8.3 [μm].

The poly-Si is chemical vapor deposited (CVD) on single crystal silicon wafer surface, and the specimens are made from surface micromachining process. Manufacturing process of specimens is shown in Fig. 3 schematically. In order to reduce residual stress, the specimens are made of 4 poly-Si layers. The gap between the cantilever and the substrate is 2 [μm].

A dynamic ultra micro hardness tester (Shimadzu Co. DUH-W201) with a Berkovich diamond indenter is used for the bending tests. The test machine is for hardness test but we can obtain the relationship between load and displacement with satisfactory accuracy by this machine. Table 2 shows the properties of the test machine. The test load speed is 1.421 [mN/sec.]. The bending tests are carried out at room temperature under the atmospheric environment.

2.2 FEM analysis

In order to quantify the fracture of specimens by the applied stresses in the tests, three-dimensional finite element elastic analyses are performed. Figure 4 indicates the examples of FEM models of the specimens (Type-A, L15R1). For the Type-B specimen, the 1[μm] corner radiuses are taken into the model based on the microscopic observations mentioned above. The stress concentration factor of Type-B is close to that of Type-A, L15R3. The element sizes of the models are about 0.5[μm] in the overall region and are about 0.1[μm] in the stress concentration area around the notch root. The analyses are carried out under the load condition such as the displacement of loading point is equal to 1[μm]. Table 3 and Table 4 show the FEM analysis conditions and material properties respectively.

**Fig. 5** Example of relationship between load and displacement (Specimen type: L15R1).

2.3 Test results

**Figure 5** shows examples of the relationship between load and displacement of the bending tests. In this figure, it is known that the polycrystalline silicon deformed elastically until final catastrophic failure in room temperature, showing a brittle nature. The relationship between load and displacement shows a little nonlinear behavior. This is because of indentation to poly-Si of the indenter.
Figure 6 shows an expression of the test results by use of maximum peak stress $\sigma_{\text{max}}$ in the notch root obtained by FEM analysis. In this figure, the plots of solid mark means the data of fracture specimens and the open mark means the data of non-fracture specimens due to the contact of free edge to the substrate surface before break. The displacement which contact occur changes with specimen, this may be because the residual stress and shape of the specimens has little difference respectively. In Fig. 6, a tendency can be seen that the plots by the $\sigma_{\text{max}}$ move down with the increase in notch radius because of the effect of the difference on the stress distribution pattern.

3. Discussion

3.1 Weibull parameters

Figure 7 shows the Weibull plots of bending strength for poly-Si. The non-fracture data are treated statistically. Figure 7 show the validity of using Weibull analysis for this study.

Figure 8 shows the scale parameters ($\beta$) of this study. If shapes of the specimen are different, then effective surface area is different. Then, the scale parameter is thought to be different. Figure 8(a) shows the validity of the effective surface. Figure 8(b) shows the same result. In Fig.8, $h = 3.5[\mu m]$ specimen shows different trend. We’ll discuss about it later.

Figure 9 shows the result of shape parameter ($\alpha$). With effective surface area, Weibull parameters ($\alpha$, $\beta$) are shown as follows.

\[
F = 1 - \exp \left\{ -A_E \left( \frac{\sigma}{\beta} \right)^\alpha \right\}
\]

where $F$ is the fracture probability, $\sigma$ is the applied stress and $A_E$ is the effective surface area that is the area of the tested part. For Weibull plots, Eq. (1) is changed as follows.
$$\ln \ln \frac{1}{1-F} = \alpha (\ln \sigma - \ln \beta) + \ln A_e$$  \hspace{1cm} (2)

Eq. (2) shows the shape parameter ($\alpha$) is independent of the effective area ($A_e$). Therefore, the shape parameter is the same when strength scattering is the same material, though effective areas ($A_e$) differ (specimen thickness differ).

In Fig. 9, though $h = 6.4$ and 8.3[$\mu$m] specimen show almost same shape parameter ($\alpha$), $h = 3.5[\mu$m] specimen show different shape parameter ($\alpha$). Therefore, it turns out that the material used for the $h = 3.5[\mu$m] specimen has different strength scattering from the material of other specimens.

Strength Reliability of Micro Polycrystalline Silicon Structure

(a) Specimen type dependency.  
(b) Specimen height dependency

Fig. 8  Scale parameters of the bending strength for poly-Si.

Fig. 9  Shape parameters of the bending strength for poly-Si.

Figure 10 shows the fracture surface and around the fracture surface of poly-Si of this study.  
Fig.10 (a) \((h = 3.5[\mu m])\) are different from Fig.10 (b, c) \((h = 6.4, 8.3[\mu m])\).  This is because the etching processes for these specimens are different.  Specimen \(h = 6.4[\mu m]\) and \(8.3[\mu m]\) are made by same DRIE (Deep Reactive Ion Etching) process, but \(h = 3.5[\mu m]\) is made by another RIE (Reactive Ion Etching) process.  Then the side surface condition of these specimen (material) are different and the shape parameters \((\alpha)\) become different between \(h = 3.5[\mu m]\) specimen and \(h = 6.4, 8.3[\mu m]\) specimen.
Figure 11 shows a fracture surface that fracture origin can be found. River line pattern\(^{11}\) can be seen on the fracture surface like other brittle materials. By river line pattern, the origin of the fracture surface is clearly shown in this picture. The fracture origin is located in side surface and not upper surface of the specimen. This is because the effect of the surface conditions.

(b) Magnification of fracture origin

**Fig. 11** Fracture origin on the side surface of the cantilever specimen \((h = 8.3 \mu m), \text{L}30\).
3.2 Fracture toughness

In order to make clear the reason of the strength scattering, analysis of the fracture surface by SEM (Scanning Electron Microscope) are performed. If the variation of the strength is dependent on the initial defect size, then calculated fracture toughness is thought to be same. Figure 12 show one example of the analysis. In this figure, in the area of fracture origin, a mirror zone \(^{11}\) came under observation. Then, we assume that the mirror zone is initial defect, stress intensity factors for the mirror zone are calculated by quarter-elliptical crack in a plate under bending mode stress distribution\(^{12}\). Figure 13 shows the results. The average of the fracture toughness is 2.1 [MPa√m]. Table 5 shows reported fracture toughness \((K_{IC})\) of poly-Si\(^{13-16}\) and single crystal Si\(^{17}\). Then the value found to be about double. Then area of mirror zone is not same as area of initial defect. But Fig.13 shows that the fracture toughness is independent on specimen shape and the value is constant to some extent. Then area of mirror zone assumed to be proportional to the initial defect.

3.3 Fracture angle

More fractographic analysis is performed. Then, we found that the angle of mirror zone is different from the principal stress surface. An example of the observation result and the definition of the angle ($\theta$) are shown in Fig.14. Figure 15 shows the relationship between fracture toughness using stress and mirror zone and the angle. In this figure dependency of the fracture toughness on the angle can be seen. The reasons are thought as follows. (1) The poly-Si crystal on the fracture origin area are different from principal stress direction (2) the poly-Si grain boundary on the fracture initiation area are different from principal stress direction.

![Fig. 14](image) Definition of fracture surface (mirror zone) angle.
4. Conclusions

In order to evaluate strength reliability of micron size polycrystalline silicon (poly-Si) structure, bending tests of cantilever beam, Weibull analysis and fracture surface analysis are performed. The test results are concluded as follows.
(1) By Weibull analysis, we found that the scatter in poly-Si bending strength made by RIE process is smaller than that of DRIE process.
(2) Effective surface area can be used for the strength of poly-Si structure qualitatively.
(3) Poly-Si strength is scattered. It depends on surface condition, crystal or grain boundary direction and some other.
